We study design challenges associated with realizing a ground state quantum computer. In such a computer, the energy gap between the ground state and first excited state must be sufficiently large to prevent disruptive excitations. Here, an estimate is provided of this gap as a function of computer size. We then address the problem of detecting the output of a ground state quantum computer. It is shown that the exponential detection difficulties that appear to be present at first can be overcome in a straightforward manner by small design changes.

#### I. INTRODUCTION

Recently, there has been intense interest among researchers in the possibility of designing quantum computers [1] that calculate using the remarkable properties of quantum mechanics [2–4]. Although the potential power of quantum computation algorithms is enticing, there is great difficulty associated with actually fabricating a quantum computer in the laboratory. A variety of schemes have been suggested [5–18] and progress has been encouraging, but the feasibility of realizing a useful quantum computer is still unclear.

In a recent paper, we proposed a novel "ground state quantum computation" approach that could circumvent some of the main problems with traditional quantum computer designs [19]. This approach replaces the progress of a usual, time-dependent quantum computation with a single, time-independent state. To see how this works, let us suppose that a quantum computation algorithm consists of the evolution of M qubits through N steps defined by  $2^M \times 2^M$  unitary matrices  $\mathcal{U}_j$ ,  $j=1,\ldots,N$ . To define the state of M qubits at one step of the algorithm requires  $2^M$  amplitudes. To describe the M qubits at every step of the algorithm, from before it begins until after it ends, requires  $(N+1)\times 2^M$  amplitudes. If we do not demand that the qubits evolve simultaneously from step to step, allowing qubit #1 be at step 2 while qubit #3 is at step 6, then  $(2(N+1))^M$  amplitudes are required to map out the development of the qubits. Let us suppose that we collect these  $(2(N+1))^M$  amplitudes into a state  $|\Psi\rangle$  defined on a Hilbert space of dimension  $(2(N+1))^M$ . This state will contain all of the information in a time-dependent quantum computation, but the state itself will be completely time-independent. Instead of developing through time in accordance with an algorithm, the state will develop through Hilbert space in accordance with the algorithm.

How can we explicitly describe this development through Hilbert space? The projection of  $|\Psi\rangle$  onto some  $2^M$  dimensional subspace will contain the  $2^M$  amplitudes necessary to describe the state of the M qubits when they are all at step 0 and have undergone no unitary evolution. Let us call this projection  $P_0 |\Psi\rangle$ . More generally, let us call  $P_j |\Psi\rangle$  the projection onto the  $2^M$  dimensional subspace that describes the state of the M qubits when they are at step  $j, j = 0, \ldots, N$ . Suppose that we define an operator  $A_{j,0}$  that carries the  $2^M$  basis vectors of the subspace associated with  $P_0$  into the  $2^M$  basis vectors of the subspace associated with  $P_j$ . Then,  $|\Psi\rangle$  develops in accordance with a quantum computation algorithm provided that

$$P_i |\Psi\rangle = \mathcal{U}_i \mathcal{U}_{i-1} \dots \mathcal{U}_1 A_{i,0} P_0 |\Psi\rangle \tag{1}$$

for j = 1, ..., N.

This formal notion makes it possible to propose a new ground state approach to quantum computation. In ground state quantum computation, we do not make a register of qubits evolve in time by subjecting it to a series of time-dependent Hamiltonians. Instead, we perform calculations by manufacturing a Hamiltonian H whose ground state develops according to the equation (1). This is described precisely in reference [19]. In that paper, an appropriate Hamiltonian H is found. It is comprised of a sum of (i) one-body terms denoted like  $h_a^k(U_{a,k})$  where  $U_{a,k}$  indicates the unitary evolution of qubit a at algorithmic step k of the calculation and (ii) two-body terms designated  $h_{a,b}^j(\text{CNOT})$  associated with a controlled not of qubit b by qubit a at step b. In [19], a possible physical realization of b is suggested using states localized on quantum dots to comprise the  $(2(N+1))^M$  dimensional Hilbert space.

This ground state, time-independent approach has the attractive characteristic that it avoids traditional decoherence problems associated with time evolution. However, it does have its own challenging aspects that need to be addressed. Many of these challenges concern the scaling of a ground state quantum computer – the feasibility of making such a

computer larger and larger. In this paper, we address two of the most important considerations involved in increasing the size of a ground state quantum computer. First, we study how the energy gap between the ground state and first excited state of the Hamiltonian H will depend on N and M. Clearly, if a ground state quantum computer is to function properly the gap must be large enough in energy that the computer will reliably remain in its ground state. Second, we investigate the problem of measuring the outcome of a ground state quantum computation. In its most naive form, a ground state quantum computer would become very difficult to probe as it grew in size. We propose several means of avoiding this difficulty.

# II. GAP

If a ground state quantum computer is raised into an excited state, its wavefunction can no longer be relied upon to satisfy equation (1), and the computer therefore does not compute correctly. To avoid such excitations, the computer must possess a sufficiently large energy gap between ground state and first excited state. The gap must be significantly larger than the available thermal energy  $k_BT$ , for example.

As a ground state quantum computer grows in size, its gap will decrease, limiting the length of practical computations. Here, we study this limit, describing the size dependence of the gap of the Hamiltonian described in [19]. We argue that the gap shrinks approximately like  $1/(N+1)^2$  and prove the existence of a lower bound that scales as  $1/(N+1)^4$ .

#### A. Single Qubit

To obtain these quantitative estimates of the gap, we first consider the case of a single qubit computer. Here, the Hamiltonian is simply  $H = \sum_{i=1}^{N} h^{i}(U_{i})$  where [19]

$$h^{i}(U) \equiv \epsilon \left[ C_{i-1}^{\dagger} C_{i-1} + C_{i}^{\dagger} C_{i} - \left( C_{i}^{\dagger} U C_{i-1} + \text{h.c.} \right) \right]. \tag{2}$$

is associated with the development of the single qubit from step i-1 to step i of the calculation. It is convenient to make a unitary transformation from the  $C_i$  operators to new operators  $(\Pi_{j=1}^i U_j)C_i$ . This changes the form of the Hamiltonian to  $H = \sum_{i=1}^N h^i(I)$  where every  $U_i$  that appears in H has been replaced by the 2 by 2 identity matrix I. To determine the eigenspectrum of this new H, we solve the determinantal equation  $\det(H-E)=0$ . The determinant is evaluated by deriving and solving a recursion relation on matrices of increasing size. We find that

$$\det(H - E) = \epsilon^{2(N+1)} \frac{k - 2 + 1/k}{k - 1/k} \left(k^{2(N+1)} - \frac{1}{k^{2(N+1)}}\right)$$
(3)

where  $k = (1 - \frac{E}{2\epsilon}) + \sqrt{(1 - \frac{E}{2\epsilon})^2 - 1}$ . Setting the determinant (3) to zero yields eigenenergies  $E = E_m \equiv 2\epsilon(1 - \cos(\pi m/2(N+1)))$ , where m is an integer between 0 and 2N+1. The ground state has energy  $E = E_0 = 0$ , and the first excited state has energy  $E = E_1 = 2\epsilon(1 - \cos(\pi/2(N+1))) \rightarrow \epsilon\pi^2/(2(N+1))^2$  for large N. Thus, the gap decreases as  $1/(N+1)^2$ . This is true for a single qubit, and also for any number of non-interacting qubits.

### B. One CNOT Gate

Of course, a useful quantum computer must have interactions among qubits, so the behavior of the gap must be examined when interactions are present. To begin, we address the case of exactly two qubits interacting through exactly one CNOT gate. The full Hamiltonian includes single qubit  $h^i(U_i)$  terms and one  $h^j(CNOT)$  interaction term at stage j.

We begin by examining the Hamiltonian with the  $h^j(CNOT)$  term omitted. Without the  $h^j(CNOT)$  term, the computer has two disjoint regions for each qubit, one "upstream" of the omitted CNOT gate consisting of stages 0 to j-1 and one "downstream" of the omitted CNOT gate consisting of stages j to N. Since an electron in one of the disjoint regions will possess the eigenspectrum of a single, non-interacting qubit, the first excited state in such a region will have an amount of energy of order  $1/(N+1)^2$ . If we neglect such "high-energy" states, only the (doubly degenerate) ground states of the two regions make important contributions to the electronic state of each qubit. This means that each qubit has four available states, leading to an effective 16 dimensional Hilbert space for the two qubit system.

It is straightforward to diagonalize the interaction Hamiltonian  $h^j(CNOT)$  analytically in this  $16 \times 16$  basis. The result is a (fourfold degenerate) ground state of the computer with zero energy, an (eightfold degenerate) first excited state with energy  $\epsilon/(j)(N-j+1)$ , and a (fourfold degenerate) second excited state with energy  $\epsilon/(N-j+1)^2 + \epsilon/(j)(N-j+1) + \epsilon/(j)^2$ . So, the energy of the gap in the 16 dimensional Hilbert space scales as  $\epsilon/(j)(N-j+1) \sim 1/N^2$ .

What relationship does the gap in this 16 dimensional Hilbert space have to the exact gap of the system? The (fourfold degenerate) ground state in this 16 dimensional Hilbert space is, in fact, the exact ground state in the whole Hilbert space. Hence, the (eightfold degenerate) first excited state in the 16 dimensional Hilbert space is actually orthogonal to the exact ground state of the system. It follows that the quantity  $\epsilon/(j)(N-j+1)$  represents a rigorous variational upper bound to the exact first excited state energy of the system.

The variational upper bound should provide a reasonable estimate of the true value of the gap. However, for our purposes we are perhaps more interested in having a guaranteed lower bound to the gap. Such a lower bound would ensure that, when less than a specified amount of energy is available, the computer will not experience a disruptive excitation. As it turns out, it is possible to show that the gap has a rigorous lower bound of  $\alpha/(N+1)^4$  for some real positive  $\alpha$ . The following is an argument by contradiction.

We know the ground state of the Hamiltonian H has energy zero. Suppose that  $|\psi\rangle$  is some state of the 2-particle system that is orthogonal the ground state of H. Assume that the expectation value  $\langle \psi | H | \psi \rangle$  satisfies

$$\langle \psi | H | \psi \rangle < \alpha / (N+1)^4 \equiv E_{\text{lower}}.$$
 (4)

To evaluate the left hand side and draw a contradiction, we split the Hamiltonian H into  $H_0$ , which consists of only single body terms, and  $H_1 = h^j(CNOT)$ , which consists of only interaction terms. Both  $H_0$  and  $H_1$ , it is straightforward to show, are positive semi-definite. Consider the form of  $|\psi\rangle$  in a basis of eigenstates of  $H_0$ 

$$|\psi\rangle = \sum_{n,i} c_{n,i} |\phi_{n,i}\rangle \tag{5}$$

where the *i* labels the degenerate eigenstates with the *n*th eigenenergy. Saying that  $|\psi\rangle$  is orthogonal to the (fourfold degenerate) ground state of H essentially means that  $|\psi\rangle$  has no contribution from the four states  $|\phi_{n,i}\rangle$  for which  $H_0 + H_1 |\phi_{n,i}\rangle = 0$ . Therefore,  $|\psi\rangle$  can consist of a superposition of eigenstates of  $H_0$  with eigenenergies greater than zero and the 12 zero energy eigenstates of  $H_0$  that are orthogonal to the (fourfold degenerate) ground state of the system.

Further reflection shows that  $|\psi\rangle$  cannot involve exclusively the 12 zero energy eigenstates of  $H_0$  because then  $\langle\psi|H|\psi\rangle$  would go like  $1/(N+1)^2$ , as we showed above, violating the assumption (4). The state must therefore possess some contributions from excited eigenstates of  $H_0$ . These states have eigenenergies of at least  $\epsilon\pi^2/(2(N+1))^2$ , as we saw in our single qubit analysis, so assumption (4) limits the contribution from such states to  $\sum_{n>0,i}|c_{n,i}|^2 < E_{\text{lower}}/(\epsilon\pi^2/(2(N+1))^2)$ . This limit exists even though  $H_1$  is present since  $H_1$  is positive semi-definite and cannot decrease the expectation value produced by  $H_0$ . Hence we find that

$$\langle \psi | H | \psi \rangle = \sum_{i,j} c_{n=0,i}^* c_{n=0,j} \langle \phi_{n=0,i} | H_0 + H_1 | \phi_{n=0,j} \rangle + \sum_{n>0,m>0,i,j} c_{n,i}^* c_{m,j} \langle \phi_{n,i} | H_0 + H_1 | \phi_{m,j} \rangle$$
 (6)

$$+ \sum_{m>0,i,j} \left( c_{m,i}^* c_{n=0,j} \left\langle \phi_{m,i} \right| H_1 \left| \phi_{n=0,j} \right\rangle + c_{n=0,i}^* c_{m,j} \left\langle \phi_{n=0,i} \right| H_1 \left| \phi_{m,j} \right\rangle \right)$$
 (7)

$$> \frac{\epsilon}{(N+1)^2} + 0 - 2\left|\sqrt{12}\right| \left|\sqrt{4(N+1)^2 - 16}\sqrt{\frac{E_{\text{lower}}}{\epsilon\pi^2/(2(N+1))^2}}\right| \frac{\mu}{(N+1)^2}$$
 (9)

here  $-\mu/(N+1)^2$  is the most negative value of  $\langle \phi_{m>0,i}|H_1|\phi_{n=0,j}\rangle$ . This last inequality contradicts the assumption (4), however, since

$$\frac{\epsilon}{(N+1)^2} + 0 - 2\left|\sqrt{12}\right| \left|\sqrt{4(N+1)^2 - 16}\sqrt{\frac{E_{\text{lower}}}{\epsilon\pi^2/(2(N+1))^2}}\right| \frac{\mu}{(N+1)^2} = \frac{1}{(N+1)^2} (\epsilon - 2\left|\sqrt{12}\right| \left|\sqrt{\frac{4(N+1)^2 - 16}{(N+1)^2}}\sqrt{\frac{\alpha}{\epsilon\pi^2/4}}\right| \mu) > E_{\text{lower}}$$
(10)

provided that  $\alpha$  is chosen to be sufficiently small. This contradiction shows that the assumption (4) is not valid. Since the ground state has energy zero, and any state orthogonal to the ground state has energy at least  $E_{\text{lower}}$ , we have a lower bound  $E_{\text{lower}}$  on the value of the gap.

### C. Arbitrary Computer

It is straightforward to apply these results to the case of M qubits interacting via an arbitrary number of CNOT gates. First of all, the variational upper bound on the gap of  $\epsilon/(j)(N-j+1)$  still holds. This is because different CNOT Hamiltonians  $h_{a,b}^j(CNOT)$  commute with one another, so we can treat each separately when diagonalizing in a basis of zero energy, M-particle eigenstates of  $H_0$ .

Now, with this division described, we are in a position to demonstrate the lower bound of order  $1/(N+1)^4$ . Suppose that some M-particle state  $|\psi\rangle$  is orthogonal to the  $(2^M$  fold degenerate) ground state of the system. It is possible to write  $|\psi\rangle$  in the form

$$|\psi\rangle = \sum_{n,i} c_{n,i} |\phi_{n,i}\rangle \tag{11}$$

where the  $|\phi_{n,i}\rangle$  are M-particle eigenstates of  $H_0$ . Because  $|\psi\rangle$  is orthogonal to the ground state of the system, each term  $|\phi_{n,i}\rangle$  that appears in  $|\psi\rangle$  must satisfy  $(H_0)_{a,b}^j + h_{a,b}^j(CNOT) |\phi_{n,i}\rangle \neq 0$  for some CNOT gate j,a,b. Let us call  $|\psi_{a,b}^j\rangle$  the sum of the components  $c_{n,i}|\phi_{n,i}\rangle$  that satisfy  $(H_0)_{a,b}^j + h_{a,b}^j(CNOT) |\phi_{n,i}\rangle \neq 0$ . If any  $|\phi_{n,i}\rangle$  could belong in more than one  $|\psi_{a,b}^j\rangle$ , we include it in every possible  $|\psi_{a,b}^j\rangle$ . Then,

$$\langle \psi | H | \psi \rangle \ge \sum_{j,a,b} \left\langle \frac{1}{2} \psi_{a,b}^{j} \left| (H_0)_{a,b}^{j} + h_{a,b}^{j}(CNOT) \left| \psi_{a,b}^{j} \right\rangle \right\rangle$$
 (12)

$$\geq \frac{1}{2} \sum_{j,a,b} \left\langle \psi_{a,b}^{j} \middle| \psi_{a,b}^{j} \right\rangle \frac{\alpha}{(N+1)^{4}} \geq \frac{\alpha}{2(N+1)^{4}} \sim \frac{1}{(N+1)^{4}},\tag{13}$$

where we have made use of the lower bound  $\alpha/(N+1)^4$  derived in the last section. The last inequality holds because every component of  $|\psi\rangle$  appears in at least one of the  $|\psi_{a,b}^j\rangle$ . This result shows that a lower bound  $\sim 1/(N+1)^4$  holds for an arbitrary number of qubits and CNOT gates.

#### III. DETECTION

The task of detecting the result of a ground state computation seems daunting at first. Each qubit in the computer must be measured in the final stage, which it only visits with probability 1/(N+1). Since there are M qubits, the probability of making a successful measurement scales as  $1/(N+1)^M$ . This problem is not, however, unsurmountable. In the following we describe several schemes that circumvent the detection scaling problems.

In the case of Grover's algorithm, or any other algorithm for which the final state of the qubits factors, it is actually possible to guarantee a successful measurement. This is accomplished by placing an additional readout electron just after the final stage of each qubit, as in Fig. 1. Since the qubit electron will be localized in one of the two dots in the final stage, the readout electron will tend to get pushed toward the other dot by the Coulomb interaction. In the ground state of the entire system, qubit electrons and readout electrons included, a readout electron will be

localized to the left (right) if its qubit is in the right (left) at the final stage. The outcome of the algorithm can always be determined by detecting the position of the readout electrons, even though the qubit electrons have only a small probability of residing at the final stage. In effect, the readout electrons are providing a continuous, passive measurement of the final state of the computer. Although this readout electron method is guaranteed to work for an algorithm for which the final state of the qubits factors, it will not work at all if the final state of the qubits does not factor. For a general algorithm, another approach is necessary.

An approach which applies to arbitrary algorithms involves the adjusting the Hamiltonian at the final stage N for each qubit a. Suppose that the operator  $C_{a,N}^{\dagger}$  is replaced by  $\beta C_{a,N}^{\dagger}$  everywhere it appears in the Hamiltonian and  $C_{a,N}$  by  $\beta C_{a,N}$ , where  $\beta$  is a small fraction. All algorithms will still work just as before, but we are "tipping" the computer toward the final stage so that the qubits reside there more often. Then, it follows that in the ground state of the system, each qubit has  $1/\beta$  times greater amplitude on the final stage than on the previous stages. The probability of detecting all qubits on the final stage is of order  $1/(1+\beta^2 N)^M$ . If  $\beta$  is set to be of order, say  $1/\sqrt{MN}$ , we find that the probability of all qubits being at the final stage goes as approximately  $(1-1/M)^M$ , which approaches  $\exp(-1)$ . It only takes two or three attempts to catch all of the qubits at the final stage.

Of course, the change in the Hamiltonian will effect the gap. If the final operators are scaled by a factor  $\beta$  then the quantity  $\det(H-E)$  of non-interacting qubits will change to

$$\det(H - E) = \epsilon^{2(N+1)} \frac{k - 2 + 1/k}{k - 1/k} \left(k^{2(N+1)} - \frac{1}{k^{2(N+1)}} + (\beta^2 - 1)(k^{2N+1} - \frac{1}{k^{2N+1}})\right) \tag{14}$$

Setting this determinant to zero, we find that the gap of non-interacting qubits still scales roughly as  $1/(N+1)^2$  for arbitrary  $\beta$  between zero and one. Once CNOT gates are included, however, the gap will have a variational upper bound of order  $1/(N+1)(N+1/\beta^2)$  and a lower bound of  $E_{lower} = \alpha/(N+1)^2(N+1/\beta^2)^2$ . If  $\beta = 1/\sqrt{MN}$ , then the upper bound is 1/(NM+N)(N+1) and the lower bound  $E_{lower} = \alpha/(N+1)^2(NM+N)^2$ .

Another technique for alleviating measurement problems is to "synchronize" the arrival of the qubits at the final stage. In our CNOT gate, the target electron cannot proceed beyond the gate until the control electron has. A controlled "identity" (CID) gate could be constructed that would function similarly, preventing a target electron from proceeding beyond the gate until after a control electron, but always subjecting the target qubit to an identity operation and never a NOT operation. With this gate, the arrival of the qubits at the final stage could be "synchronized." Suppose that each qubit controls the entry of the next qubit to a ground state quantum computer's final stages, using a CID gate. Then, whenever qubit M is found in the final stage, all qubits are there. This could be useful for detection schemes, although it would not enhance the overall probability of finding the qubits at the final stage of the computer.

## IV. CONCLUSION

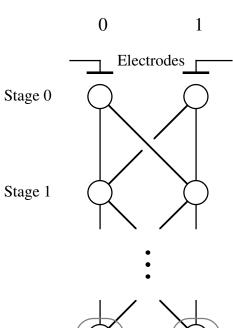

In this paper, we have explored some important challenges to constructing a ground state quantum computer. First, we found upper and lower bounds for the energy gap between the computer's ground state and first excited state. The bounds provide guidelines to making a computer of a specified size that can be relied upon to remain in its ground state. Next, several schemes were presented for easing qubit detection difficulties. These schemes indicate how to probe a ground state quantum computer so that it will yield output with certainty or at least high probability. It is hoped that the analysis of energy gap and detection in this paper complements our initial proposal and eases the task of designing and fabricating a ground state quantum computer in the laboratory.
